Abstract. We study the multi-armed bandit problem, where the aim is to minimize the simple regret with a fixed budget. The Sequential Halving algorithm is known to tackle it efficiently. We present a more elaborate version of this algorithm to integrate some exterior knowledge or "scores", that can be provided for instance by a neural network or a heuristic like all-moves-as-first (AMAF) in the context of Monte-Carlo Tree Search. We provide both theoretical justifications and experiments.

1 Introduction

Since it was introduced in [6, 11], the Monte Carlo Tree Seach (MCTS) algorithm has known a great success in AI, especially in turn-based games like Go or Chess, and some of its refinements are the state of the art for most games.

The general idea of this algorithm is the following: on the root configuration, pick a move, and generate a random playout from it. If the player to move wins, this means that the move was probably good, and if she loses it was probably bad. Then loop by picking more moves, deeper and deeper in the game tree, with a fixed amount of playout (or time) budget.

One of the keys for MCTS to be efficient is to choose what moves to investigate, with the usual exploration vs exploitation balance to find. To perform this, one typically uses the Upper Confidence Bound (UCB) bandit algorithm, which has good properties in terms of cumulative regret. This means that, for every investigated configuration, the moves tested were overall not bad.

However, in the context of games, the success of simulations does not really matter. The only aim is that, at the end, the algorithm outputs a move that is as good as possible. This means that, instead of cumulative regret, a more relevant quantification is the expected simple regret (see Fig. 1 for a precise definition).

In [10], a new bandit algorithm named Sequential Halving (SH) was introduced. It is proved to have a small expected simple regret 0-1 (see Fig. 1), and it experimentally shows to also have a small expected simple regret. It has successfully been used as an alternative to UCB in MCTS, especially as a replacement in the root with UCB used in the rest of the tree [12], in Partially Observable Games [13] or even is the whole tree with SHOT [3].

However, for most games, the plain UCB is not state of the art. For many games like Go, moves typically commute, so the RAVE algorithm was introduced [9], which uses the all-moves-as-first (AMAF) heuristic [1]. For some games also including Go

[14], Neural Networks (NN) can provide the algorithm with reliable priors, which are incorporated in the PUCT algorithm [14].

The aim of this paper will be to incorporate exterior knowledge like AMAF or NN to the SH algorithm, and to compare the result both to plain SH and to the state of the art MCTS algorithms RAVE and PUCT.

The first part will discuss the SH algorithm in general, and report experiments in a theoretical setup. The second part will present a theoretical foundation for a new algorithm named SHUSS, Sequential Halving USing Scores. It will also discuss some variations around it, and report experiments on games.

Fig. 1: The various notions of regret

With p_i the mean of arm i, i^* the optimal arm and $\hat{i}$ the chosen one,

- Cumulative regret : $\mathcal{R}_{\text{cum}} = \sum_{r \text{ round}} (p_{i^*} - p_r)$
- Simple regret : $\mathcal{R} = p_{i^*} - p_{\hat{i}}$
- Simple regret 0-1 : $\mathcal{R}_{0-1} = 1$ if $i^* \neq \hat{i}$ else 0

2 The Sequential Halving algorithm

The SH algorithm is round-based. On every round, each arm is sampled the same amount of times, and then some fraction of the worst arms is removed, until there is only one arm left.

The theoretical bounds presented in [10] suggest that the same total budget should be spent for each round, and that the fraction removed should be constant on every step (denoted $1 - \lambda$). For a precise description, see Algorithm 1.

This version of the algorithm is slightly different from the original in two ways. First, a parameter λ is introduced, while it was fixed to 1/2. Second, the computation of the budget per round is slightly improved, to ensure that less budget is left unspent in case of multiple roundings.

Note 1. Contrary to other bandit algorithms like UCB, SH gives a lot of budget at once to each arm, which has practical advantages like an easier parallelism and less back-and-forth in the search tree. This is especially true when there are few rounds (λ small).

2.1 Restart vs stockpile

In [10], for the theoretical computations to be rigorous, one has to assume that rounds are independent, which means that statistics are discarded from one round to the other.

However, to gather more accurate statistics, it may be worth, instead of *restarting* at every round, to *stockpile* the statistics from the previous round. In terms of budget, this adds a factor almost $1/(1 - \lambda)$.

Note 2. Getting the factor almost $1/(1 - \lambda)$ from the first rounds implies to twist the distribution of weight to give more at the beginning, but less at the end. Doing this will be referred to as *uniforming*.

Algorithm 1 Sequential Halving

Parameter: cutting ratio λ
Input: total budget T, set of arms S
$S_0 \leftarrow S, T_0 \leftarrow T$
$R \leftarrow$ number of rounds before $|S_R| = 1$
for $r = 0$ **to** $R - 1$ **do**
  $t_r \leftarrow \lfloor \frac{T_r}{|S_r| \cdot (R-r)} \rfloor$
  $T_{r+1} \leftarrow T_r - t_r |S_r|$
  sample t_r times each arm in S_r
  $S_{r+1} \leftarrow S_r$ without the fraction $1 - \lambda$ of the worst arms
end for
Output: arm in S_R

In theory, this may cause the following issue: if, on one round, a rather bad arm is lucky and has good stats, it will be stockpiled for the next round and cause it to be kept even further; while if we restarted it would be rare that an arm is lucky twice. This issue is especially important when λ is close to 1, as the stockpiled statistics form a huge part of the overall ones.

In addition to the two extremes, one can keep the statistics from the previous round, and give it a decaying factor d between 0 (pure stockpile) and 1 (pure restart).

Experiments of the next section clearly show that stockpiling is always the best, even better than $0 < d \ll 1$.

Note 3. We successfully replicated the SH part of the experiments of [10], and it appears that they must have been done using stockpiling, as restarting gives significantly worse results.

2.2 Experiments

Even if we could be more general, we focus on the case where the only possible outcomes are 0 (loss) and 1 (win). Thus, every arms is described by its *value*, which is both the probability of win and the expected value.

The performance of bandit algorithms highly depend on the distribution of the arm's values. We consider 4 settings for the n arms.

In setting (1), the optimal arm has a value 0.5 and the $n - 1$ others have a value 0.4.

In setting (A), the values form an arithmetic sequence from 0.5 to 0.25.

In setting (S), the optimal arm has a value 0.5, the worst has a value 0.25, and the others have values such that i/δ_i^2 is constant, with δ_i the difference with the optimal arm. This setting is suggested by the fact that the theoretical bounds of [10] rely on these values, and thus the theoretical guaranty is the strongest.

In setting (N), the values are distributed according to the sigmoid of a normal of parameters 0.5 and $\sigma^2 = 0.01$. This setting induces richer behaviours, and we believe it to be a more realistic model of the actual distributions in games.

The results are compared to UCB, the standard MCTS bandit. It consists in, for each step from 1 to the budget, picking the arm that maximises the empirical value, plus a term to force exploration of the form

$$c\sqrt{\frac{\log(\text{playouts})}{\text{playouts}_z}}$$

We tested various values for λ and d for SH, and compared it to various values for the exploration constant c in UCB. We also tested the uniforming variant discussed in Note 2. The results are shown in Fig. 2.

Roundings of the number of arms left are handled as follows: always round up, except when this would cause the amount of arms to remain constant (then round down).

Each result is averaged over 10000 tests. To reduce the covariance from one setting to another, the bandits are seeded using *numpy.random.binomial*. For the same index of experiment e and the same arm i, if the value of arm i is the same in two settings, then on the same round r their results are drawn out of the same sequence of win/loss (the number of successes is monotonic in terms of budget).

As announced, in every setting, the best results are obtained for $d = 0$, so that in practice stockpiling is really stronger than restarting.

The optimal λ depends on the setting. The experiments globally suggest that, for the interesting case $d = 0$, $\lambda \approx 0.7$ is often the best value, but the difference is small and the algorithm performs well on a wide range of λ that includes the classical value $\lambda = 0.5$. Actually, this is a very complex problem, and some less rigorous experiments suggest that it is better not to decrease like a geometric sequence but rather to start with large decreasing factors and to end with smaller ones (eg $20 \to 8 \to 4 \to 3 \to 2 \to 1$ rather than $20 \to 10 \to 5 \to 3 \to 2 \to 1$).

Uniforming's effect is mixed, which suggests that there is room for practical improvement about how the budget is distributed among the rounds.

Surprisingly, the results are globally worse than UCB for $n = 20$, especially in the setting (S) while this is the one for which the SH algorithm is theoretically designed. Still, UCB relies more heavily on a fine-tuning of its parameter c, with no universally excellent value, and for $n = 80$ SH is globally better.

3 Scores

The aim of this part will be to develop a variant of the SH algorithm that makes advantage of some exterior knowledge, like a NN or AMAF statistics. We will consider the general case where we have access to what we will call a *score*, which is a numerical evaluations of every move, independent from the bandit evaluation.

The bandits are still assumed to give either 0 or 1, giving an empirical mean $p_r^{(i)} \in [0, 1]$ for arm i on round r, but the scores do not necessarily belong to $[0, 1]$.

3.1 Theoretical model

We don't know precisely how to estimate the expected simple regret: the bounds provided in [10] are far from tight in practical cases and only describe the expected simple regret 0-1. Still, it will globally depend on $P(p_r^{(i)} < p_r^{(j)})$: if any two arms are often

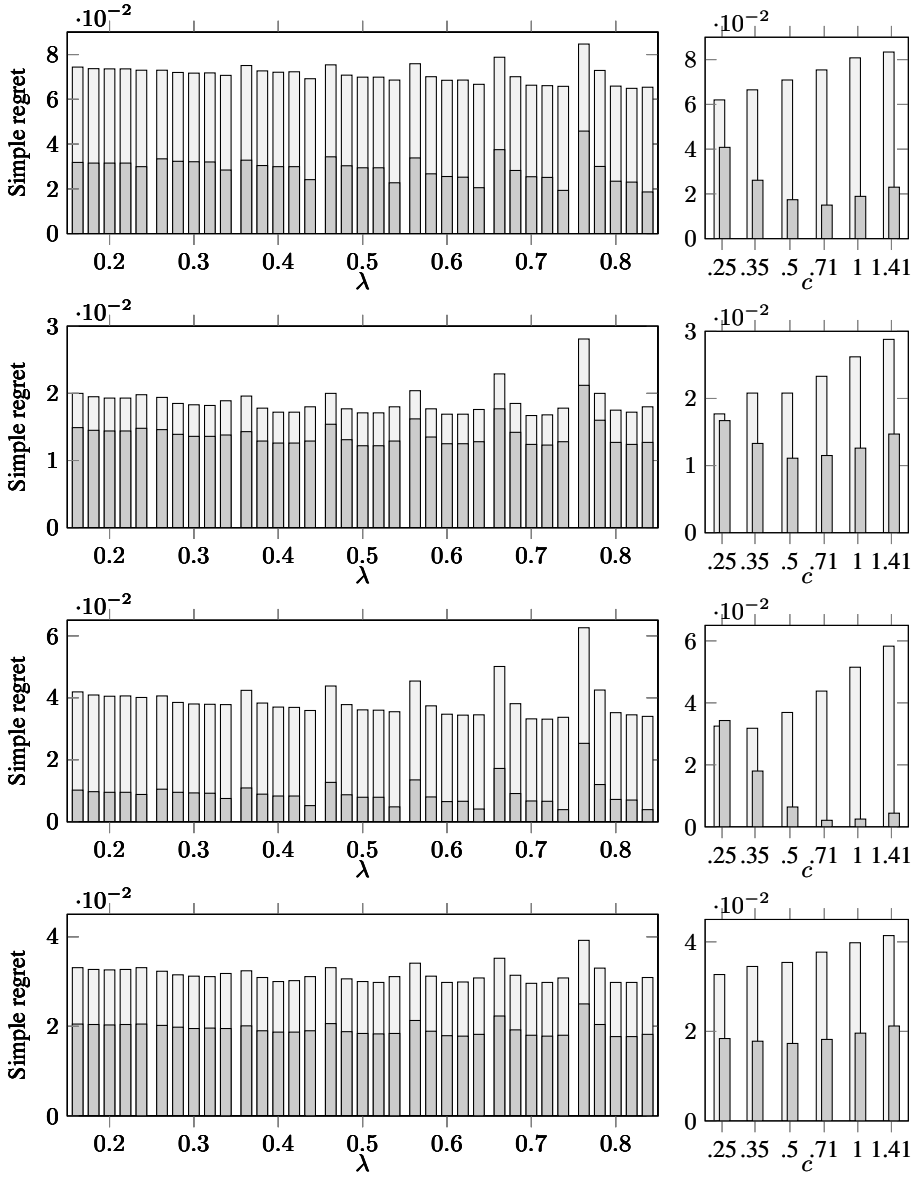

Fig. 2: Simple regret obtained with SH in various settings. In every setting, the budget is taken equal to $T = 2048$. From top to bottom, we report settings (1), (A), (S) and (N). For each setting, the left plot corresponds to SH, and the right one corresponds to UCB. For SH, for each λ, the bars correspond (from left to right) to $d = 1$, $d = 0.5$, $d = 0.1$, $d = 0$, and $d = 0$ with uniforming. The darker bars correspond to $n = 20$, and the lighter ones to $n = 80$.

properly ordered, then the best arms have a low probability to be among the worst $1-\lambda$ fraction. Thus, our aim will be to find an optimal formula for some replacing $q_r^{(i)}$ which optimizes $P(q_r^{(i)} < q_r^{(j)})$.

Formally, let x and y (the value of the arms) be two hidden values that we want to compare, with $x - y = \delta$. We have access to 4 independent variables. X and Y (the number of 1 obtained) are binomials with a same first parameter t and centered on respectively tx and ty. $\tilde{X}$ and $\tilde{Y}$ (the scores, eg the AMAF statistics) are such that $\tilde{X} - \tilde{Y} = \tilde{\delta}$ is hopefully globally the same sign as δ.

In the following, z can stand for x, y, or any arm.

We make the assumption that $\tilde{\delta}$ is distributed following a normal law with parameters $\tilde{\delta}_0$ and $\tilde{\sigma}_0^2$. $\tilde{\delta}_0$ has the same sign as δ, and we even have $\tilde{\delta}_0 = \delta$ when the score is unbiased. This is not the case for NN, but we will see how to handle this in Section 3.5.

3.2 Optimal combination

As a particular case of the central limit theorem, we know that (for a more quantified statement, see for instance [7]):

Lemma 1 *A binomial law of parameters t and p and a normal law of parameters tp and $tp(1-p)$ have almost the same distribution, provided that t is large.*

This means that $X - Y$ is (almost) distributed as a normal law of parameters $t\delta$ and $t\sigma^2 = t(x(1-x) + y(1-y))$, which up to normalisation can be seen as having parameters $\tilde{\delta}_0$ and $\frac{\tilde{\delta}_0^2\sigma^2}{\delta^2 t}$.

Conversely, this shows that $\tilde{X} - \tilde{Y}$ gives (almost) the same information as two binomials, with the crucial first parameter $\tilde{t}$ such that

$$\tilde{\sigma}_0^2 = \frac{\tilde{\delta}_0^2\sigma^2}{\delta^2\tilde{t}}$$

This gives

$$\tilde{t} = \frac{\tilde{\delta}_0^2\sigma^2}{\delta^2\tilde{\sigma}_0^2}$$

but with the intensity is $\frac{\tilde{\delta}_0}{\delta}$ too large.

We define

$$\tilde{t}' = \frac{\tilde{\delta}_0\sigma^2}{\delta\tilde{\sigma}_0^2}$$

We showed that the problem is (almost) equivalent to maximizing the probability to choose the best arm among two, knowing that one has succeeded $X + \tilde{t}'\tilde{X}$ times out of $t + \tilde{t}$ trials, and the second $Y + \tilde{t}'\tilde{Y}$ times.

Thus, it is optimal to use (for $\frac{\tilde{\delta}_0^2\sigma^2}{\delta^2\tilde{\sigma}_0^2}$ reasonably large)

$$q_z = Z + \tilde{t}'\tilde{Z}$$

A similar reasoning gives the same result for t reasonably large.

One could be tempted to use the $\tilde{Z}$ to approximate σ. However, given the final goal is to sort all the arms on one single scale, $\tilde{t}'$ has to be the same for every pair of arms.

The simplest solution is to choose an hyperparameter $\tilde{t}'$ that corresponds to an overall reasonable guess. We will see how to improve it in some particular cases.

The resulting algorithm is presented as Algorithm 2. In this algorithm, t_r^+ corresponds to the total budget used in $p_r^{(i)}$: $t_r^+ = t_r$ with restart and $t_r^+ = t_0 + \cdots + t_r$ with stockpile.

Algorithm 2 Sequential Halving USing Scores (SHUSS)

Parameter: cutting ratio λ, $\tilde{t}'$
Input: total budget T, set of arms S, online scores $\tilde{X}_r^{(i)}$
$S_0 \leftarrow S, T_0 \leftarrow T$
$R \leftarrow$ number of rounds before $|S_R| = 1$
for $r = 0$ **to** $R - 1$ **do**
  $t_r \leftarrow \lfloor \frac{T_r}{|S_r| \cdot (R-r)} \rfloor$
  $T_{r+1} \leftarrow T_r - t_r |S_r|$
  sample t_r times each arm in S_r, giving an empirical mean $p_r^{(i)}$ to arm i out of t_r^+ trials
  $q_r^{(i)} = p_r^{(i)} + \frac{\tilde{t}'}{t_r^+} \tilde{X}_r^{(i)}$
  $S_{r+1} \leftarrow S_r$ without the fraction $1 - \lambda$ of the worst arms in terms of $q_r^{(i)}$
end for
Output: arm in S_R

3.3 Selection bias

One issue that may occur with this algorithm is that, after some round, the arms that remains have their $\tilde{Z}$ biased by the fact that they were among the best. Thus, even if at the first round they are indeed normal laws, it is unclear how they look like after a few rounds.

However, this issue is very similar to the issue of stockpiling, as all arms tend to have better stats than they should. The fact that stockpiling is so powerful suggest that this issue is not too important, so we will neglect it.

3.4 Case of AMAF: a better formula for $\tilde{t}'$

This subsection discusses the special case where the scores are given by AMAF statistics. It should be seen as a little toolbox of a few ideas that can be used to do better than taking $\tilde{t}'$ as a constant, based on a case study.

The AMAF (all-moves-as-first) score [1] consists to evaluate a move m for a player p in a game state s, considering the win/loss ratio of every game where p plays m, not

only in s itself but in any of its descendants in the game tree (or even its cousins, in some variants of AMAF like GRAVE [2]).

First of all, this score is not independent from the value of the bandits. In the first rounds of the algorithm, there are many bandits, so the AMAF scores are almost independent from each of them, which makes it not a big issue.

In the last rounds, however, it is highly correlated with the stats of some, if not all, bandits. In some games, one could imagine that some properties of the moves generate important biases, for instance if the move m can only appear after few of the remaining moves considered. We will see a general way to address this problem, but this could be more tricky for some particular games and we recommend cautiousness.

The main interesting thing about AMAF in this context is that the score is more and more accurate as evaluations are performed. Thus, taking $\tilde{t}'$ as a constant throughout the algorithm is not appropriate. Instead, one can model the distribution of $\tilde{\delta}$ as follows:

- the fact that AMAF is a heuristic causes an error distributed a a normal law of variance σ^2_{heu}, centered somewhere between δ and the local average value;
- the fact that the AMAF stats are only gathered on a finite number s_r of moves on round r causes an error distributed as a binomial law, which is almost (see Lemma 1) and after normalization a centered normal law of variance $\sigma^2_{\text{stat}}/s_r$.

Provided that σ^2_{heu} is small (i.e. the heuristic makes sense in the application context), and the values of the arms are not too extreme, σ and σ_{stat} are almost equal.

The same formula for $\tilde{t}'_r$ as before applied with this variance give

$$\tilde{t}'_r = \frac{\tilde{\delta}_0}{\delta} \frac{\sigma^2}{\sigma^2_{\text{heu}} + \sigma^2_{\text{stat}}/s_r} \approx \frac{\tilde{\delta}_0}{\delta} \frac{1}{\sigma^2_{\text{heu}}/\sigma^2 + 1/s_r}$$

This time, we have 2 hyperparameters to choose.

$\frac{\tilde{\delta}_0}{\delta}$ describes how much AMAF flattens the stats, and can easily be measured experimentally. It may be relevant to make it depend on the number of arms left and on the variant of AMAF used.

$\sigma_{\text{heu}}/\sigma$ describes how accurate the heuristic is, compared to the accuracy provided by binomial stats. Taking this hyperparameter as a relatively high value also ensures that, in the last rounds where s_r is large, the value of $\tilde{t}'_r$ stops increasing, which addresses the previously mentioned issue of correlation.

Note that this reasoning works only if, on each round, s_r is globally the same for every arm (or if, for every arm, $1/s_r \ll \sigma^2_{\text{heu}}/\sigma^2$), as we need a common value of $\tilde{t}'_r$.

3.5 Case of prior score: pruning

In this subsection, we assume that the $\tilde{X}_i$ are known a priori (before any evaluation is performed). This can be applied to some extent in cases where some score is known a priori but refined during the algorithm, like GRAVE. We start with a general discussion, and then the specific case of neural networks (NN) applied to MCTS will be treated.

Even before the algorithm begins, some arms have no chance of being chosen at the end, for instance if $\tilde{X}_i$ is smaller than the median (for $\lambda = 1/2$) minus $1/\tilde{t}'_0$.

In addition to these trivial pruning, it is often worth to prune some more arms, as the budget saved will compensate for the risk taken.

As we saw in a previous section, the prior can be interpreted as if we have already spent some amount $\tilde{t}$ of budget on each arm before round 0, which we will consider as a round number -1. The philosophy of SH (exploited in the performance proof in [10]) is that, when bandits are pruned up to number n_r with a budget t_r, the product $\pi_r := n_r \cdot t_r$ is equal to some π that does not depend on r. Thus, it is natural to prune up to arm n_{-1}, where n_{-1} is chosen so that $\pi_{-1} = \pi$.

For a precise computation, we neglect the rounding issues when dividing by λ. We also make the computations as if we were not stockpiling (note that using the score on the further rounds can be seen as stockpiling when it is purely a prior).

Then

$$\pi_{-1} = n_{-1} \cdot \tilde{t}$$

$$\pi = \pi_0 = \lambda n_{-1} \cdot \frac{T}{\log_{1/\lambda}(n_{-1}) \cdot n_{-1}}$$

$$n_{-1} \log_{1/\lambda}(n_{-1}) = \frac{\lambda T}{\tilde{t}}$$

For NN in MCTS, all the previous theoretical foundation has to be slightly adapted, given bandits don't give 0 or 1 but instead the value of the leaf evaluated by the NN.

More importantly, the score is given by the policy of the root. It is meant to be monotonic with the value, but the way it uses a softmax layer makes the rest of our model about its distribution fail. Thus, the safer way to use it is for pruning, and then the remaining arms are explored using a basic SH that does not use the policy.

The previous formula for n_{-1} should hold for the same reasons. Now, the value of $\tilde{t}$ describes how many budget is needed for the exploration to be as good as the policy. As the budget is typically attributed in the rest of the tree by an algorithm like PUCT designed to be good asymptotically but not for small values, $\tilde{t}$ is typically quite large. In addition, given the policy is not stockpiled, it is better to overestimate the value of $\tilde{t}$ to make use of the policy as much as possible.

3.6 Experiments with AMAF

First, we test SHUSS using the score AMAF, to compare it with RAVE [8, 9].

The latter uses the AMAF score as follows: the value of the arm, which the exploration term is added to, is taken equal to

$$(1 - \beta_z)Z + \beta_z \tilde{Z}$$

with t_z the number of playouts starting with z, s_z the number of playouts containing z and

$$\beta_z = \frac{s_z}{s_z + t_z + bias \times s_z \times t_z}$$

[12] demonstrates how to combine the SH algorithm with UCT in the Hybrid-MCTS algorithm: SH is used only at the root, and the rest of the tree expansion uses

Table 1: Percentage of games won by Hybrid-SHUSS (using AMAF and RAVE) against RAVE, in various games.

UCB. We followed this idea, by combining SHUSS at the root with RAVE for the rest of the tree, in an algorithm naturally named Hybrid-SHUSS.

Table 1 reports the results of 500 matches (250 as White and 250 as Black) between Hybrid-SHUSS and RAVE, for many classical games. Both algorithms use a budget (number of playouts) per move equal to 10000. RAVE uses the classical parameter $bias = 10^{-7}$, both in the inner parts of Hybrid-SHUSS and its opponent. SHUSS uses the classical parameter $\lambda = 1/2$.

Different values of $\tilde{t}'$ are experimented (to keep things simple, $\tilde{t}'$ is a constant). The extreme case $\tilde{t}' = 0$ is the usual SH algorithm without AMAF (it is only used to break ties), and $\tilde{t}' = \infty$ is relying purely on AMAF, with the same weight whether or not the move is first.

In most games, SHUSS performs better than both pure SH and pure AMAF.

The optimal value of $\tilde{t}'$ depends on the game, but using 1024 gives a reasonably good performance for every game with this budget.

3.7 Experiments with a neural network

Then, we test SHUSS with a prior given by a NN in the game of Go.

The state of the art NNs in the game of Go use two heads, one for the policy and one for the value. The MCTS algorithm used in current computer Go programs since AlphaGo is PUCT. It uses the NN score as follows : the exploration term is replaced by

$$c \times \tilde{Z} \times \frac{\sqrt{t}}{1 + t_z}$$

with $\tilde{Z}$ the policy, t the budget already used for this node and t_z the budget already used for this node on move z.

We use as a NN a simple MobileNet of 16 blocks, a trunk of 64 and 384 planes in the bottleneck block [4, 5]. This model gives better result than usual residual networks for the game of Go.

As explained in section 3.5, in SHUSS, the policy is used to prune at the root, and the remaining algorithm is SH at the root and PUCT for the remaining of the tree, in a similar Hybrid fashion.

Experiments showed that PUCT performs best against Hybrid-SHUSS for $c = 0.2$. Table 2 report the results of 400 matches of Hybrid-SHUSS against PUCT for various budgets and n_{-1}, and we see that with the Hybrid-SHUSS outperforms PUCT for large enough budgets.

Concerning the relationship between T and the optimal n_{-1}, it looks logarithmic, while it was theoretically expected to be close to linear. Still, the size of the game of Go forced us to stick to rather small budgets, for which this part of the theory may not apply yet as it is asymptotic.

4 Conclusion

In the first section, we have discussed the SH algorithm in general.

We discussed two ways of using the budget, stockpiling and restarting, and the first is experimentally way better.

We also showed that a cutting parameter $\lambda \approx 0.7$ for SH is experimentally slightly better than the classical $\lambda = 0.5$, but globally the algorithm is very robust for a wide range of λ. Still, it appears that some more flexible budget attribution or cuts may be better.

In the second section, we presented our new algorithm Sequential Halving USing Scores (SHUSS).

A theoretical model suggests a very simple way to combine the score with the bandit statistics, but there is plenty of room for improvement depending on the score.

Work still has to be done to handle scores that are very asymmetrical among the arms in terms of quality.

We made SHUSS associated to AMAF statistics and RAVE under the root play at many different games against RAVE with the same parameters. The results are mixed, and depend on the game.

We made also SH that prunes using the policy and PUCT under the root play Go against PUCT with the same parameters. SH with pruning outperforms PUCT for well chosen numbers of moves kept, but it is quite sensitive to this value and it is unclear how to choose it in general.
